ABSTRACT
Much work in knowledge extraction from text tacitly assumes that the frequency with which people write about actions, outcomes, or properties is a reflection of real-world frequencies or the degree to which a property is characteristic of a class of individuals. In this paper, we question this idea, examining the phenomenon of reporting bias and the challenge it poses for knowledge extraction. We conclude with discussion of approaches to learning commonsense knowledge from text despite this distortion.

Categories and Subject Descriptors
I.2.6 [Artificial Intelligence]: Learning—Knowledge Acquisition; I.2.7 [Artificial Intelligence]: Natural Language Processing

Keywords
Knowledge extraction; text frequency; reporting bias

1. INTRODUCTION
In Artificial Intelligence, it seems that the human-like understanding and reasoning required for problems such as question-answering, recognizing textual entailment, and planning depends on access to a large amount of general world knowledge. The difficulty of accumulating such a collection is known as the knowledge acquisition bottleneck. While there have been attempts to manually engineer suitable knowledge (as in the Cyc project [22]) or to solicit it directly from crowds online (as in the Open Mind Initiative [30]), the dominant approach is to mine knowledge from the extensive text available in electronic form.

A system can look for explicit assertions of general knowledge or knowledge implicit in recurrent patterns of predication and modification, or it can abstract general claims from collections of specific instances. Regardless of the modus operandi, it is necessary to distinguish knowledge about what normally holds in the world from the atypical or claims that are simply not true. For instance, the Knext [27] system for knowledge extraction from text (described in Section 4) learns both The Earth may revolve around the Sun and The Sun may revolve around the Earth. Mistaken claims like this latter may indicate a failure to correctly learn from text (e.g., if a source said ‘It is not the case that the Earth revolves around the Sun’), or it may result from reading an inaccurate or fantastical text.

To identify good claims, it is typical to take an inductive view, with textual references serving as evidence: The more often we read something, the more likely it is to reflect what is true in the real world. This is intuitively reasonable, and, over a large collection of texts, Knext learns the heliocentric claim 327 times, while the geocentric claim is only learned 126 times. However, the frequency with which situations of a certain type are described in text does not always correspond to their relative likelihood in the world, or even the subjective frequency captured in human beliefs. For instance, from the same texts, Knext learns almost a million times that A person may have eyes, but fewer than 1,600 times that A person may have a spleen. While eyes are discussed frequently, many other body parts are not — but this doesn’t mean they’re any less common in people. We will refer to this potential discrepancy between reality and its description in text as reporting bias.¹

For knowledge extraction (KE), we are interested in reporting bias as it relates to the frequency with which events or actions occur, the likelihood of specific outcomes, and the prevalence of properties. If our textual examples are not representative of reality, then claims induced from them are likely to be inaccurate. For instance, according to Douglas Lenat, at one point Cyc “concluded that everyone born before 1900 was famous, because all the people that it knew about and who lived in earlier times were famous people.” [23]

While the focus of this paper is on how reporting bias affects the acquisition of general knowledge, many of the phenomena we discuss also apply to factual information extraction (IE). E.g., frequently reading claims that Barack Obama was born in Kenya does not make it a reliable extraction. However, for a factual IE system, other extraction properties may be more salient than textual frequency. For instance, the great frequency of statements that George Bush is the president of the United States should not lead us to believe this is currently true, given the greater recency of sentences indicating Obama is president. The trustworthiness of text sources can also be of greater importance for factual IE than for general knowledge extraction, which can abstract claims even from realistic fiction.

2. MEASURING REPORTING BIAS
To demonstrate the reality of reporting bias and motivate our discussion in the next section, we will give several examples where the frequencies of textual references and extractions differ significantly from what we know to be the case in the world. Giving a full, accurate model of reporting bias or establishing how widespread the problem is would require the availability of real-world frequencies across...

the range of types of properties that we are interested in learning from text. Instead, we simply demonstrate the existence of significant reporting bias for actions or events, outcomes, and properties.

We present textual frequencies based on the Google Web 1T n-gram data [3], which is derived from approximately a trillion words of Web text, circa 2006. We support this, where possible, with the number of times Knext learns a relevant claim about the world. These results are taken from a knowledge base of 73 million unique factoids learned from sources including the Brown Corpus [21], the British National Corpus [2], Gigaword [24], Project Gutenberg books, Wikipedia, and the ICWSM 2009 weblog corpus [4]. The full knowledge base is available to browse at http://cs.rochester.edu/research/knext/browse.

In the introduction, we used the example of how often we are told a person has spleen vs having eyes. In Table 1, we see the significant variation with which body parts are mentioned in text, though they are near universally present in individuals. While this type of knowledge is readily available from manually created sources such as WordNet [13] or Cyc [22], the fact that even such simple extractions exhibit significant reporting bias bodes ill for the long tail of more subtle knowledge that we are less likely to be able to enumerate.

For instance, KE systems may try to learn from text the typical frequency of an event or how characteristic an action is of a class of individuals, to produce generic claims such as Generally people sleep or Most people sleep daily, while only Some people play the viola. However, in Table 2, we see that murder is mentioned in text many more times than more quotidian actions like hugging or constant activities like breathing; and we find people are late much more than they are on time. The Knext extraction frequencies can be seen as a further distortion of the textual frequencies, due, at least in part, to the filtering of potential claims. For instance, factoids about murder are automatically discarded if they lack the complement (i.e., you need to murder someone).

Another important kind of knowledge is the expected outcome of an action or event, e.g., If a person drops a glass, it may break. As this knowledge relies on larger patterns of predication, often involving more than one sentence, it is not easily measured on a large scale. However, in Table 3 we see that, per mile travelled, a person is more likely to experience a crash on a motorcycle than in a car or in an airplane. However, in text motorcycle crashes are only mentioned half as frequently as plane crashes.

For a simpler example, we know that for most races (whether foot races, political contests, etc.) the number of winners is less than or equal to the number of losers, yet we find far more reports of a person winning a race than losing it: In the n-grams, won the race occurs more than six times as often as lost the race (66,011 vs 10,430). The number of matches for (participated in | ran in | took part in | entered the race), which lack the stigma of “losing”, is still quite low (22,512). Even for the Academy Awards, where “it’s an honor just to be nominated”, people are much more likely to write about a win than a nomination. We find won the academy award 15,098 times vs 4,551 for nominated for the academy award (and the same is true for a number of variations, such as academy award winner and academy award winning).

3. DISCUSSION

We believe these discrepancies between reality and textual frequency indicate a pervasive distortion. Reporting bias results from our responsibility as communicators to be maximally informative in what we convey to other people, who share our general world knowledge, and to convey information in which they are likely to be interested.

The first of these imperatives was postulated by Paul Grice [18] as his conversational maxim of quantity. This states that communication should be as informative as necessary – but no more, leaving unstated information that can be expected to be known or can be inferred from what is said using commonsense knowledge. Havasi et al. [19] previously knowledge acquisition from text to Gricean principles, noting that “people tend not to provide information which is obvious or extraneous” and, therefore, “it is difficult to automatically extract common-sense statements from text, and the results tend to be unreliable”. The second imperative – to be interesting – is less a linguistic principle than a psychological or social one: Some topics are intrinsically interesting to people, regardless of their prevalence, and we will tend to discuss these, biasing what information is available in text.

To elaborate and clarify this discussion, we offer these hypotheses about reporting bias with corresponding examples:

1. The more expected something, the less likely people are to convey it as the primary intent of an utterance.

People are unlikely to tell you about ‘the man with two legs’ or ‘a yellow pencil’. Rather, we state exceptional properties: ‘a man with one leg’, ‘a blue pencil’. Similarly, we don’t say ‘I paid for the book and then I owned it’ or ‘A suicide bomber blew himself yesterday. He died.’ as these are assured consequences. We might, however, say, ‘crashed my car. It was totalled.’ as the degree of damage is not certain otherwise. While expected information is unlikely to be the primary purpose of an utterance, it can appear in presuppositions; see Section 5.
2. The more value people attach to something, the more likely they are to give information about it, even if the information is unsurprising.

For instance, in a report of forest fires sweeping parts of California, we care about homes destroyed, and people killed or injured, but most care less about the number of chipmunks or deer killed. Further, the destruction of thousands of acres of forest will often matter and will be mentioned, as would the loss of members of a rare animal species. If we describe a person we met, we may well say he has brown hair even though this extremely common. However, we are even more likely to mention a person’s hair color if it’s unusual: While textual references to brown hair are more frequent than red (594,997 to 382,989 in the Google n-grams), the latter’s representation is quite disproportionate to its occurrence in the population.

3. Conversely, even unusual facts are unlikely to be mentioned if they are trivial.

E.g., having a scratch on the left bicep may be less common than an interesting, important property like a woman being pregnant, but it usually matters too little to be reported.

4. Reporting bias varies by literary genre.

There will be considerable differences in the frequency of reporting events in an encyclopedia vs in fiction or even, e.g., among different newspapers. While sports pages will “over-report” sporting events compared to crimes, celebrity shenanigans, or business news, the National Inquirer or the Wall Street Journal might over-report other types of events.

5. There are fundamental kinds of lexical and world knowledge that are needed for understanding and inference that don’t get stated in text.

This can be because they are innate or are learned before language is acquired, by physical interaction in the world. E.g., physical objects can’t be in different places at the same time; solid objects tend to persist (in shape, color and other properties) over time; if A causes B and B causes C then it’s usually fair to say that A causes C; people do and say things for reasons – to get food or possessions or pleasure, to avoid suffering or loss, to provide or solicit information, etc.; you can’t grab something that’s out of reach; you can see things in daytime that are nearby and are not occluded; people can’t fly like birds or walk up or through walls; etc.

There are also the lexical entailments and presuppositions that we learn as part of language and hardly ever say: ‘above’ and ‘below’, ‘bigger’ and ‘smaller’, ‘contained in’ and ‘contains’, ‘good’ and ‘bad’, etc., are incompatible; dying entails becoming dead; going somewhere entails a change in location; walking entails moving one’s legs, etc.

4. PREVIOUS APPROACHES

In looking at how systems have dealt (or not dealt) with reporting bias, we want to contrast three lines of work: information extraction systems [7, 26], which learn explicitly stated material; knowledge extraction systems (e.g., [34]), which abstract individual instances to the general knowledge that’s implicit in them; and systems that learn general rules implicit in a collection of specific extractions (e.g., [25, 33, 5]). We only provide a few examples; for a more thorough overview, see [32].

**TextRunner**

TextRunner [1] is a tool for extracting explicitly stated information as tuples of normalized text fragments, representing verbal predicates and their arguments. TextRunner’s output includes both information about specific individuals and generic claims. Based on the number of distinct sentences from which a tuple was extracted, it is assigned a probability of being a correct instance of the relation. TextRunner’s authors view the probabilities assigned to these claims not as representing the real-world frequency of an action or the likelihood the relation holds for an instance of a generic subject, but simply as the probability that the tuple is “a correct instance of the relation”. It’s not clear what this means for their “abstract tuples”, which are 86% of the output on average, per relation, and include claims such as (Einstein, derived, theory) or (executive, hired by, company). Is this a correct instance if Einstein at any point derived a theory? What if any executive was at some point hired by a company? Or is an abstract tuple only a correct instance of the relation if it is a good generic statement, e.g., Executives are (generally) hired by companies?

**Knext**

Knext [27, 34], under development since before 2002, is a tool for extracting general world knowledge from large collections of text by syntactically parsing each sentence with a Treebank-trained parser (e.g., [6]) and compositionally applying interpretive rules to compute logical forms in a bottom-up sweep, abstracting those that serve as stand-alone propositions. (It’s sufficient to consider it a more logically formalized set of interpretive rules than the later Stanford Dependencies [8, 9], leading to generic knowledge similar to that targeted by systems subsequent to Knext, such as NELL [5].) The results are quantificationally underspecified Episodic Logic formulas, which are verbalized in English as possibilistic claims, e.g., Persons may want to be rid of a dictator.

Knext treats all discovered formulas as possible general world knowledge. In an evaluation of 480 propositions, Van Durme et al. [34] observed that propositions found at least twice were judged more acceptable than those extracted only once. However, as the support increased above this point, the average assessment stayed roughly the same. That is, frequency of extraction was not found to be a reliable indication of quality.

Later work [14] has sharpened Knext output into explicitly quantified, partially disambiguated axioms. This uses the pointwise mutual information between subject terms and what’s predicated of them as one of the factors in determining appropriate quantifier strength. However, this association is overruled by semantic patterns, e.g., having a body part is (near-)universally true for a class of individuals even if – as with people’s spleens – it is rarely mentioned. For individuals such as having a possession, these sharpened axioms are subject to the distortion of reporting bias.

**Urns**

TextRunner’s probabilities use the Urns model of Downey et al. [12, 11], which is based on the belief that an extraction is more likely to be true if it is obtained from multiple documents, adjusting for how often a type of reference occurs. E.g., Urns should assign a lower probability to ‘countries such as Washington’ (31 hits on the Web) than it does to ‘throwable objects such as bean bags’ (3 hits) given the far greater number of extractions for countries than for throwable objects (example due to Doug Downey). However, Urns is meant to establish the truth of ground facts (e.g., Einstein was born in 1879), not the probability of a generic claim applying (e.g., People eat food). Indeed, a great deal of the commonsense knowledge we want to learn is only discovered a handful of times, even over Web-scale text, while Urns requires a fairly large sample size for each relation.

**Learning Rules from Extracted Facts**

A line of work at Oregon State University [29, 10] learns domain-particular rules based on specific facts extracted from text. They
We've shown that reporting bias's distortion of real-world frequency weight rules, based on the idea that more accurate rules usually have were born in Canada.) But if, in fact, \( B(x) = b' \), then we are likely to say so. (E.g., we would say \('an Egyptian-born Canadian'.)"

Along similar lines, Raghavan and Mooney [25] learn commonsense knowledge in the form of probabilistic first-order rules from the incomplete, noisy output of an information-extraction system. Their rules have a body containing relations that are often stated explicitly, while the head uses a relation that is mentioned less often as it's easily inferred. They produce rules like hasBirthPlace\((x, y) \land person(x) \land nationState(y) \rightarrow hasCitizenship(x, y)\). An interesting aspect of their approach is the use of WordNet similarity to weight rules, based on the idea that more accurate rules usually have predicates that are closely related in meaning.

### 5. ADDRESSING REPORTING BIAS

We've shown that reporting bias's distortion of real-world frequency in text makes it doubtful that we can interpret the number of textual references or explicit statements supporting a general claim as directly conveying real-world prevalence or reliability. While there seems to be no silver bullet, there are some approaches to learn what normally holds in the world. For instance, we can focus extraction on more informative constructions:

1. **Presuppositions.** Commonsense knowledge that is rarely stated explicitly can nonetheless appear in sentences as presuppositions — beliefs the speaker expects others to share:
   
   "Both my legs hurt.
   →\( A \) person normally has two legs.

   I forgot the money to buy groceries.
   →\( A \) person may use money to buy things.

2. **Disconfirmed expectations.** Gordon & Schubert [15] learned commonsense inference rules from constructions that indicate a speaker's expectation about the world was not met, e.g.,
   
   "Sally crashed her car into a tree but wasn't hurt.
   → If a person crashes her car, she may be hurt.

   'I dropped the glass, but it didn't break.'
   → If a person drops a glass, it often will break.

Other sentences suggest that an action or event has not taken place with the normal temporal frequency [16]:

"I hadn't slept in days.
→ A person normally sleeps at least daily.

(These claims are implicitly conditioned on whether the agent does the action at all, e.g., If a person writes a book at all, he probably does so every few years.)

3. **Implicit denials.** Explicit statements, pragmatically required to be informative, contain implicit denials that what they're saying is usually the case, e.g.,
   
   "The tree had no branches.'
   → Trees usually have branches.

However, these vary in how easily they can be transformed into general claims, e.g.,

"Molly handed me a blue pencil.'
→ Probably pencils are not always blue.

4. **Reference to individuals.** Expected properties can be expressed when identifying a particular individual, e.g.,
   
   ‘...the man I met yesterday.'
   → A person may meet a man.

Claims frequently learned from such constructions may be more usual than those learned from more explicit assertions, though there are still many more references to a 'plane that crashed' than a 'plane that landed'.

More correlation might be seen between frequency and extraction quality if we only count the frequency of distinct textual references. E.g., repeated mentions of the film True Lies, misparsed as a common noun phrase, lead Knext to learn Lies may be true. Even if text is analyzed correctly for its surface meaning, it can lead to bad knowledge, e.g., the idiom 'when pigs fly' gives us Pigs may fly. A related problem is frequently repeated text, such as song lyrics on the Web. To account for this textual bias – exact repetition – we might give more weight to knowledge learned from different extraction methods or just from distinct constructions.

Another possibility is to use a hybrid approach to knowledge extraction, along the lines of [28] or [20]. For instance, we might combine text mining with a crowdsourced rating [17] or filtering stage to assign an approximate real-world frequency to the knowledge found most frequently in text. Work in the emerging "grounded language" movement may also be important. If one were to say 'John entered the room', they are unlikely to follow it up with 'He blinked. He breathed.' However, many mundane actions and activities might be recognized, e.g., by sampling video and be incorporated into our knowledge.

It is also important to recognize that for some problems, frequencies for the distorted world described in text are more useful than real-world frequencies. For instance, a parser is concerned with how frequently a particular construction is analyzed correctly for its surface meaning, it can lead to bad knowledge, e.g., the idiom 'when pigs fly' gives us Pigs may fly. A related problem is frequently repeated text, such as song lyrics on the Web. To account for this textual bias – exact repetition – we might give more weight to knowledge learned from different extraction methods or just from distinct constructions.

### 6. CONCLUSIONS

We have argued that researchers need to be aware that the frequency of occurrence of particular types of events or relations in text can represent significant distortions of real-world frequencies and that much of our general knowledge is never alluded to in natural discourse. We provided a brief pragmatic argument for why reporting bias exists, which led to suggestions on how we might, partially, work around it.

Our examples and discussion are meant to provoke further study. If reporting bias is not a real problem for knowledge acquisition, it remains for the community to show this to be the case. Otherwise, more work is called for to determine if, and how, we can correct for it. At worst, reporting bias may prove an upper bound on the extent to which human knowledge can be learned from text and may provoke further work on hybrid approaches to knowledge acquisition.
